IPTS WORKING PAPERS ON CORPORATE R&D AND INNOVATION - No. 02/2013

The production function of top R&D investors: Accounting for size and sector heterogeneity with quantile estimations

Antonio Vezzani and Sandro Montresor

2013

European Commission Joint Research Centre Institute for Prospective Technological Studies

The IPTS WORKING PAPERS ON CORPORATE R&D AND INNOVATION address economic and policy questions related to industrial research and innovation and their contribution to European competitiveness. Mainly aimed at policy analysts and the academic community, these are scientific papers (relevant to and highlighting possible policy implications) and proper scientific publications which are typically issued when submitted to peer-reviewed scientific journals. The working papers are useful for communicating preliminary research findings to a wide audience to promote discussion and feedback.

The IPTS WORKING PAPERS ON CORPORATE R&D AND INNOVATION are published under the editorial responsibility of Fernando Hervás, Pietro Moncada-Paternò-Castello and Andries Brandsma at the Knowledge for Growth Unit – Economics of Industrial Research and Innovation Action of IPTS / Joint Research Centre of the European Commission, Michele Cincera of the Solvay Brussels School of Economics and Management, Université Libre de Bruxelles, and Enrico Santarelli of the University of Bologna.

The main authors of this paper are Antonio Vezzani (JRC-IPTS, European Commission, Seville, Spain) and Sandro Montresor (JRC-IPTS, European Commission, Seville, Spain and department of economics, University of Bologna, Italy).

Abstract

The paper investigates how top R&D investors differ in the production impact of their inputs and in their rate of technical change. We use the EU Industrial R&D Investment Scoreboard and perform a quantile estimation of an augmented Cobb-Douglass production function for a panel of more than 1,000 companies, covering the period 2002-2010. The results for the pooled sample are contrasted with those obtained from the estimates for different groups of economic sectors. Returns to scale are bounded by the initial size of the firm, but to an extent that decreases with the technological intensity of the sector. The output return of knowledge capital is the most important, irrespective of firm size, but in high-tech sectors only. Elsewhere, physical capital is the pivotal factor, although with size variations. The investigated firms appear different also in their technical progress: embodied in mid-high and low/mid-low tech sectors, and disembodied in high-tech sectors.

Keywords: production function; R&D; firm and sector heterogeneity.

JEL codes: D24; D21; 030.

Introduction

The micro-econometric estimate of the production function – that is, the technical relationship between the firm's inputs (e.g. labour and capital) and its output (i.e. good or service) – represents an important tool of analysis. The marginal contribution of different production factors to the economic outcome of the investigated firms can be analysed and compared, as well as the elasticity of substitution between them. Furthermore, the kinds of returns to scale (i.e. increasing, constant, or decreasing) from which they benefit (or suffer) can be detected. Finally, the rate of technical progress that the firms show over time can at least be inferred.

In spite of their importance, these production-related aspects are not receiving much attention in current micro-economic studies, which have recently been re-oriented towards the analysis of the firm's technical efficiency and its economic impacts (Green, 2008; Kumbhakar *et al.*, 2012).¹ The production function is becoming "a tool, a framework for answering other questions, only partially related to [it]" (Griliches and Mairesse, 2005, p. 2). In micro-innovation studies, in particular, the analysis of the production function has been overshadowed by that of its "knowledge" counterpart (Griliches, 1979).²

The burden of the econometric problems that affect the estimation of the production function is certainly an obstacle to pursuing its investigation (Griliches and Mairesse, 2005). Among the several issues, that of its identification and of the endogeneity (simultaneity) problems entailed by the possibility of unobservable determinants of production has attracted most of the attention.³

Although possibly less recognised than the aforementioned, another obstacle to the study of firms' production function is represented by the inner heterogeneity that firms have been found to show in both their production and knowledge activities (Loof and Heshmati, 2002).

¹ Technical efficiency can be defined as the effectiveness with which production factors are used to produce an output. A firm is said to be technically efficient if it is generating a given amount of output making use of the minimum possible quantity of inputs, such as labour, capital and technology.

 $^{^{2}}$ As is well known, the so-called "knowledge production function" estimates the outcome of the innovative activities of the investigated firms.

³ In the last 15 years, for example, the use of instrumental variables and of fixed effect estimation has been enriched by the dynamic panel literature (in the seminal work by Arellano and Bond, 1991) and on the use of observed input decisions (in the study by Olley and Pakes, 1996).

Firms of different size show inherently different capacities for turning their inputs into production output and additional diversity comes from their different sectors of activity. While there are ways to integrate them in order to account for this heterogeneity, econometric estimates of a parametric kind are not fully equipped to accurately illustrate its impact on production. However, less standard semi-parametric techniques can be used for this scope and interesting implications can be obtained from them.

The present paper focuses on the heterogeneity of firms' production function. Its aim is to show how quantile regression can be a useful analytical tool for a micro-econometric estimate that tackles firms' heterogeneity directly. In general, among other properties, the quantile regression allows one to draw a comprehensive picture of the effect of predictors on a response variable, for different ranges of its values. In our specific case, the quantile estimation can help us in detecting how far the production impact of firms' inputs varies along different firm size quantiles and in different economic sectors.

In the paper we carry out this estimate on a sample of more than 1,000 top R&D investors over the period 2002-2010, representing nearly 80% of total world R&D. Their high R&D intensity makes of them a sample of firms with substantial innovative efforts (in brief, highly innovative, if we use an input kind of proxy for innovation) and with a relatively homogenous pattern of innovation (i.e. relying on internal and formal innovative efforts). Furthermore, the ranking criterion with which the sample is built up leads it to be dominated by large (at most, medium) companies. Given these common features, one could argue that their production behaviour and performance are relatively homogeneous and that their eventual policy support should require a similar kind of action. These considerations make our search for heterogeneity in the production function of these firms – both in terms of size and sector of economic activity – particularly interesting. Should we actually find traces of it, the exercise that we propose would become even more compelling for a more general kind of sample.

Far from constituting a test for the underlying hypotheses of the production function, or a search for the most accurate specification for it, the paper intends to show how by relying on a simple specification for it (as we will see, a standard Cobb-Douglas specification), new insights can be drawn about the production process of the investigated firms. In general,

we shed new light on the extent to which returns to scale and factor shares differ depending on the firms' size and economic sector, providing additional stylised facts that industrial dynamics should retain. More specifically, we contribute to the empirical evidence on the heterogeneity of innovative firms, pointing to interesting differences even among the most intensive R&D spenders, which should integrate the explanation of their different performance. These two aspects represent the main value added by the paper and are translated into new policy and strategic implications for supporting firms' innovation and growth.

The rest of the paper is organized as follows. Section 2 outlines the literature to which our analysis more directly contributes. Section 3 illustrates the data and the econometric methodology. Section 4 reports and discusses the results. Section 5 concludes with a set of policy implications.

Theoretical background

In spite of important regularities, firms of different size and economic sectors show different behaviours and performances. As far as R&D and innovation are concerned, this result dates back at least to the work of Joseph Schumpeter in the previous century. The subsequent debate on Schumpeter Mark I – innovation mainly comes from small-medium enterprises in monopolistically competitive markets – vs. Schumpeter Mark II – large companies in oligopolistic markets have a lead in R&D – has provided new evidence and theoretical arguments on this issue (e.g. Breschi et al., 2000). Distinct sectoral systems of innovation have been identified, in which firms of different size compete within different market structures, and with different innovation opportunities, appropriability regimes, exploitable knowledge bases and cumulativeness conditions (Malerba, 2002).⁴

Size and sector specificities have also been identified by looking at innovation diffusion among firms. From the seminal Pavitt taxonomy (Pavitt, 1984), up to the most recent sectoral classification in terms of innovation (Castellacci, 2008), the differences that firms show in terms of internal and external knowledge sources, technology transfer, and

⁴ Important elements of analysis have also been provided by the specific literature on the role of market structure for R&D and innovation (e.g. Kamien and Schwartz, 1982).

innovation strategies (to mention a few) have been also (although not uniquely) related to their size and to the techno-economic characteristics of their sector of activity.⁵

Further elements of analysis have been obtained by the estimates of the so-called "knowledge production function" (Griliches, 1979; Griliches, 1998). Size and sector have systematically appeared robust controls for the impact that firms' innovative inputs (in particular, R&D expenditures and spillovers) have on their innovative output (e.g. patents) (e.g. Czarnitzki et al., 2009). Similar specificities have emerged by looking at the impact of firms' innovations (technological and organizational) on their performances (Evangelista and Vezzani, 2010; 2011).⁶

The results of all these studies are extremely helpful to tailor policy actions, in such a way as to target firm- and sector-specific failures in innovation. For example, with respect to Europe, public support to R&D can (and should) be informed by the finding that the innovative performance of small firms and of firms belonging to low-tech sectors is mainly driven by an embodied kind of technological change (e.g. Conte and Vivarelli, 2005; Ortega-Argilés et al., 2009).

Although it has received less attention, substantial heterogeneity should also be expected by looking at the production function that innovative firms of different size and sectors use in employing their inputs for obtaining their production (rather than innovative) output.

First of all, innovative firms of different size could benefit (suffer) from returns to (diseconomies of) scale to a different extent. The standard (i.e. labour-capital based) microeconomic argument would suggest that smaller firms are better placed to benefit from increasing returns to scale, whereas larger ones could suffer from decreasing returns due to technical inefficiencies and/or managerial costs. However, in firms which heavily invest in innovation – like the top R&D investors that we are investigating – the crucial role that knowledge capital plays, especially in relation to an increase in their scale of operation, could alter this picture. This relates to quite an established argument in industrial studies (Scherer, 1965; Acs and Audretsch, 1987), which the results of the new growth theories

⁵ The different innovation patterns shown by large firms in "scale-intensive" sectors (such as, for example, the automobile sector) and small-medium firms in "supplier-dominated" ones (for example, in textiles and furniture) is an evident illustration of this heterogeneity. ⁶ Similar insights have been obtained by looking at "extended" forms of knowledge production functions, especially in the context of regional and urban studies (e.g. Ponds et al., 2010).

about R&D spillovers and returns to scale (e.g. Aghion and Howitt, 1992) have reinvigorated. Furthermore, the techno-economic features of the sectors in which the firms operate - and their intensity of physical and knowledge capital, in particular - could introduce differences in the way returns to scale emerge along their size distribution. The evidence from applied studies in industrial organisation on the relationship between returns to scale and stages of technology/product development (e.g. Utterback and Abernathy, 1975), along with that on the different technological bases of economic sectors (e.g. Breschi et al., 2000), makes this argument relevant too.

A second point concerns the marginal returns of the factors that firms use in production, which are also supposedly size- and sector-specific. For example, the indivisibilities to which capital investments are generally exposed (Tone and Sahoo, 2003) would suggest that, compared to that of labour, their production impact is higher in larger than in smaller firms. However, in firms that invest in innovation, the marginal contribution of knowledge capital is expected to play an important role too and show a different impact at different size levels. By spreading the fruits of their projects over a larger level of output, bigger firms could be expected to have higher returns from R&D (Cohen and Klepper, 1996). Conversely, smaller firms may benefit from more creative R&D projects and have more technical scope for their exploitation (Acs and Audretsch, 1987). Once more, sector specificities matter too. In spite of the innovative character of the firms, different sectoral characteristics could affect the relative importance of different production factors, and interact with size-specific patterns of production. Following Cohen and Klepper (1996), the relationship between R&D and size should be weaker in industries where innovation may lead to a stronger growth or where innovations are more sealable in a disembodied form.

Last, but not least, in spite of the constraints that the estimate of the production function can impose on this kind of detectable technical change (which we will discuss in the next section), its rate is expected to be variable along the observed distribution of firms and to show differences across sectors as well. Although only indirectly, this is suggested by the emerging studies on the heterogeneity of the innovative output of manufacturing firms and of their patterns of economic growth (Ciriaci et al., 2012; Coad and Rao, 2008).

6

All in all, the support provided by the extant literature to the heterogeneity that firms show in production-related issues is significant but scattered. To attempt to find more general insights, in the next section we propose and carry out an empirical application that, by using the quantile regression approach, presents firms' heterogeneity in production more systematically.

Empirical application

We estimate the production function of a sample of firms contained in the EU Industrial R&D Investment (IRI) Scoreboard (<u>http://iri.jrc.ec.europa.eu/</u>). This is a scoreboard analysis of top R&D investors, in Europe and in the Rest of the World, that the Institute of Prospective Technological Studies (IPTS, Joint Research Centre, European Commission) conducts annualy since 2004. By integrating the yearly Scoreboards with other data from IRI sources, and by merging them, we have obtained a panel of 1,024 companies, over the period 2002-2010.⁷

The sample is made up of large companies (28,016 employees on average), which, however, show appreciable size variation across different sector groups. Firms in high-tech sectors (i.e. with an R&D intensity higher than 5%)⁸ are comparatively smaller (14,835 employees on average) than those in medium/high-tech (R&D intensity between 2% and 5%, with 32,048 employees on average) and medium/low ones (R&D intensity lower than 2%, with 48,386 employees on average) (Tables A1 and A2). Size heterogeneity is also relevant within sectors. The within-sector standard deviation of employment is appreciable (38,942, 54,910, and 77,820, for the three sector groups) and median values are much lower than their respective mean averages (3,034, 11,821, and 21,742, respectively). The groups of sectors that we have identified in terms of R&D intensity are also heterogeneous when we look at the different economic activities that they encompass (Table A2). However, although with some degree of approximation (mainly due to the firms' size), the technological base that they share can be traced back to that of the Pavitt (1984)

⁷ Every year the Scoreboard reports firms' accounting information for the previous four years. The panel is slightly unbalanced, due to the fact that some of the actual R&D top investors were not present in the ranking during the earlier years (e.g. HTC).

⁸ Consistently with the IRI Scoreboard, R&D intensity is here defined as the ratio between R&D investments and turnover. Its threshold values for identifying sector groups are also drawn from the IRI Scoreboard.

taxonomy. All of these elements will have to be considered in interpreting the results of our empirical application.

Following the bulk of the literature, for the sake of analytical tractability and ease of interpretation, we adopt a Cobb-Douglas formulation for the production function of firm *i* at time *t*, augmented to include R&D-based "knowledge capital", that is:

$$Y_{it} = A_t K_{it}^{\alpha} RD_{it}^{\beta} L_{it}^{\gamma} e^{ui_t}$$
(1)

Y denotes the firms' production output (measured in terms of turnover), *K* and *RD* physical and knowledge capital stocks, respectively. A_t represents the technology in use and is defined as $A_t = Ae^{\rho t}$, where *t* is the time index and u_{it} represents the systematic component of the unmeasured factors, assumed to be randomly distributed. *a*, β , γ , and ρ are the parameters of interest.

As is well known, the Cobb-Douglas production function is the unique linearly homogeneous function which entails constant factor shares (or marginal rates of return) and a unitary elasticity of substitution: two hypotheses that are hardly satisfied in empirical applications. Although an intrinsic limitation, we have opted to stick to it as a price to pay in order to illustrate, in an intuitive way, the kind of heterogeneity (i.e. in terms of size and sector) we are interested in.⁹

In equation (1), *K* and *RD* are built up using the perpetual inventory method (Hall and Mairesse, 1995). For each firm *i* at time *t*, the relevant *Stock* is defined by the following formulas:

$$\operatorname{Stock}_{it=2002} = \frac{I_{it=2002}}{\bar{g}+\delta} \quad \text{for } t = 2002 \quad (2)$$
$$\operatorname{Stock}_{it} = \operatorname{Stock}_{it-1}(1-\delta) + I_{it} \quad \text{for } t > 2002$$

where t = 2002,..., 2010. For each kind of *Stock* (*K* and *RD*), *I* represents the relative investments observed in the sample, \overline{g} is their sectoral average growth rate, and δ the

⁹ A more flexible functional form, among those which are used in micro-econometric estimations (Battese and Broca, 1997), while remedying the flaws of the Cobb-Douglas production function, does not have the advantages of analytical tractability we are able to exploit with the latter.

depreciation rate of capital. Following the extant literature (Hall and Mairesse, 1995), δ has been set to 15% for knowledge and 8% for physical capital, respectively.¹⁰

Taking the logarithms of (1), we get the following estimation equation, where small letters stand for logarithms:

$$y_{it} = a + \rho t + \alpha k_{it} + \beta r d_{it} + \gamma l_{it} + u_{it}$$
(3)

A list of dummy variables, at the industry (ICB, Industry Classification Benchmark, 4-digit level), time and country level, is included in the estimation.

Consistently with the use of the Cobb-Douglas functional form, the parameter ρ of equation (3), which captures output variations over time not accounted for by changes in the use of inputs, is taken to measure the firm's rate of technical progress. The inclusion of industry, country and, above all, time controls, enables us to be confident that such a linear trend actually captures the (constant) technological shift experienced by firms over time.

Equation (3) is estimated with a quantile model - discussed below - and the relative results are compared with those obtained using another three standard approaches: 1) Ordinary Least Squares (OLS), 2) Panel Random Effects (RE), and 3) Panel Random Effects with Instrumental Variables (IV RE).

Among the possible alternatives, as usual OLS is taken to represent a sort of benchmark estimate. RE, on the other hand, has been chosen in order to have a specification comparable to that of the focal quantile in terms of controls, given that the Hausman test did not provide evidence for supporting an alternative fixed effect model. Finally, IV RE is motivated by an attempt to account for the possible endogeneity of the production inputs. In this respect, we applied an instrumental variable approach within a panel framework. Each input has been instrumented with the t-1 lagged value of: its own and the other production inputs, and all the other regressors.¹¹

 $^{^{10}}$ Robustness checks with respect to different choices of δ have been carried out and results hold true irrespectively of them.

¹¹ Other specifications, including additional lags for the independent variables, provide not dissimilar results for the coefficients and have thus been discarded as they reduce the number of observations.

With respect to these alternative models, the quantile model has some important properties with respect to the issue at stake (Koenker and Bassett, 1978; Koenker and Hallock, 2001). First of all, it is robust against outliers and non-normal distributed errors. Second, it allows us to estimate different measures of central tendency and statistical dispersion. Furthermore, and of greater relevance for our subject, it gives a more comprehensive picture of the relationship between variables, by directly accounting for firms' heterogeneity across the sample. Indeed, the way heterogeneity is accounted for by the quantile approach is substantially different from the other models. As is well known, OLS estimations simply assume that unobserved heterogeneity exclusively derives from sector-, time-, and country-specific factors. The RE approach, conversely, assumes that there is an important source of heterogeneity coming from time-invariant, firm-specific factors, which can be accounted for by the idiosyncratic part of the error term (i.e. in equation 3, instead of estimating $a + u_{it}$, we estimate $a_i + u_{it}$). ¹² Unlike the aforementioned models, the quantile approach directly controls for that part of the firms' heterogeneity that derives from sector and country-specific factors and explicitly models it in terms of the independent variable levels. In brief, the parameters in equation 3 are allowed to vary across the firm distribution in terms of size. Accordingly, an important part of the firms' heterogeneity within a specific sector (and country) is taken to derive from their size.

In analytical terms, we are interested in estimating $Q_{\tau}(y_{it}|x_{it}) = x_i^{'}\beta$, that is the τ^{th} conditional quantile of y_{it} given x_{it} . This can be done by solving the following problem:

$$\hat{\beta}_{\tau} = \operatorname{argmin} \sum_{i=1}^{n} \rho_{\tau}(y_{it} - x'_{it}\beta) \qquad \text{where } \rho_{\tau} = u_{it}(\tau - \mathbf{1}_{(u_{it} < 0)})$$

By increasing τ continuously, from 0 to 1, it is possible to trace the entire distribution of y, conditional on x (our RHS variables).

¹² For the sake of completeness, a fixed effect approach would consider the heterogeneity as completely determined by firm-specific factors, not allowing for the inclusion of additional time-invariant controls (e.g. sectors, time and country dummies).

Results

The results of the quantile estimation provide us with interesting insights about some important issues raised by the production function analysis.

The first issue that arises is the analysis of returns to scale, measured by the extent to which a firm's production output varies with respect to the same joint variation of all its inputs. As is well known, depending on the former being more, equally, or less than proportional to the latter, these returns are said to be increasing, constant or decreasing, respectively. Benefiting from the properties of the Cobb-Douglas production function, we tested for whether the sum of the coefficients attached to the production factors is statistically different from 1 and looked at its actual value.¹³

Compared to more standard estimates, which suggest that returns to scale are generally constant (OLS and IV RE) or even increasing (RE), the quantile estimate points to important elements of heterogeneity in their specification (Table 1).¹⁴

Insert Table 1 around here

First of all, when we consider the entire size distribution of the observed firms, and we pool together firms of different sectors along it, evidence of decreasing returns is found at the top of the distribution. Although average-based estimators hide this result, some "few" quantiles of the investigated top R&D spenders (the largest 25% of them) appear to have overcome their minimum efficient scale of production. Consistently with standard microeconomic arguments, this result holds true for the largest firms of the whole distribution, while for initial and intermediate quantiles we find evidence of increasing and constant returns to scale, respectively. Interestingly, the distribution of the whole sample 'mimics', although with a right-hand side skewness, the inverted U-shape curve that returns to scale display in textbooks with respect to the production quantities of the representative firm.

¹³ Constant returns to scale hold when the null hypothesis is not rejected, whereas increasing and decreasing returns hold when the null hypothesis is rejected and the sum of the coefficients is greater and smaller than 1, respectively.

¹⁴ In looking at and interpreting the estimated coefficients, it should be noted that they give information about the marginal changes that do not move an observation from its current quantile to another quantile of the distribution.

This first result reveals important specifications when we look at returns to scale for different quantiles of firms within different groups of sectors (Table 2).

Insert Table 2 around here

On the one hand, in the high-tech sectors, the case of decreasing returns disappears even from the largest portion of the relative size distribution. Such a distribution reveals at worst constant returns, after showing increasing returns up to the median. A similar pattern holds true for firms operating in the mid-high tech sectors, in which firms switch from increasing to constant returns at a lower tail of the relative size distribution. On the other hand, in the low/mid-low tech sectors, we do not detect increasing returns at all, not even for the smallest firms. Conversely, the largest firms of these sectors appear to be the ones that account for the evidence of decreasing returns to scale that we have found above.

If we combine this last piece of evidence with the descriptive statistics of the sample (Table A1), an interesting general result emerges. Sector-specific levels of technology and firm size intertwine in determining the technical constraints to growth. Moving from low- to high-tech sectors, technological knowledge makes the constraints on returns to scale less stringent, while progressively smaller firms are more suitable to benefit from them.

A second set of results of our estimates concerns the marginal returns of the single inputs that firms use in production. The analysis of their output elasticity provides us with some important insights in this last respect. First of all, also in these cases, standard (average-based) estimates (OLS and RE) are not a reliable account of what happens along the firms' size distribution. These estimates, according to which the firms under investigation increase their output to a larger extent by increasing their physical rather than knowledge capital,¹⁵ is confirmed only by the largest firms of the whole sample (Figure 1.a). At the median quantile, the difference in the coefficients is not statistically significant. Moreover, an opposite result holds true for the first half of the size distribution, where the returns to physical capital are substantially lower than those of knowledge capital. The increasing

¹⁵ The elasticity of output with respect to physical and knowledge capital calculated with OLS is 20% and 17%, respectively. RE estimates further exacerbate this difference (see Table 1).

(decreasing) impact that physical (knowledge) capital has along the distribution completes what can be deemed an expected picture.

Insert Figure 1 around here

The smallest innovative firms of the whole sample are apparently unable to get relatively high returns from the exploitation of their physical capital. Conversely, investing in R&D from relatively lower scales of production has a greater economic impact for them (Figure 1.a). The opposite can be said of the larger firms. Increasing the scale of their plants and machinery turns out relatively more productive to them than investing more in R&D. This is another interesting result of our quantile analysis, from which the economic exploitation of the R&D investments of firms seems to prize (charge) the innovative mode of smaller (larger) companies. Once again, however, the quantile estimates per group of sectors introduce important specifications in this last respect (Figure 2).

Insert Figure 2 around here

In mid-high (Figure 2.b) and low/mid-low sectors (Figure 2.c), the results of the averagebased estimators seem to be confirmed along the quantiles: the output elasticity of physical capital is higher than that of knowledge capital, and this is also true, though to a lesser extent, for the smallest companies of the relative distribution (that is, the first quantiles of it). This might be explained by the technological regime of these sectors – in some way traceable to scale-intensive (mid-high) and supplier-dominated (low/mid-low) sectors – and their intensity of physical capital. Furthermore, we should consider that, as the sample descriptive statistics show, the firms in these two groups of sectors have a larger size on average and could thus be better equipped for dealing with the indivisibility of physical capital investments. This is particularly evident in mid-high sectors (Figure 2.b), where the output elasticity of *K* gets increasingly higher for larger quantiles of firms. On the other hand, consistently with the results from the whole sample, in both sectors the returns to R&D decrease with firm size.

In the high-tech sectors (Figure 2.a) – and in this case only – the contribution of knowledge capital is larger than that of physical capital along the whole size distribution of the sample

(with the limited exception of the very largest companies). In other words, for these firms, the sectoral pattern of innovation is such that R&D-based, technological knowledge is the key factor in terms of production, irrespective of firm size; i.e., in these sectors, the different ways in which small and large firms have been found to exploit their R&D investments do not appear to be as important. All in all, this is another interesting, although expected, result, which supports other evidence on corporate R&D investments in high-tech sectors in Europe (Ortega-Argilés et al., 2009; Moncada-Paternò-Castello, 2011).

These results on the output elasticity of *K* and *RD* are even more interesting if we link them with the size and sector variations in the economic impact of labour (*L*). The whole sample of firms appears subject to an expected increase in mechanisation/automation in line with increased firm size (Todd and Oi, 1999): labour appears to be substituted by physical capital along the corresponding distribution (Figure 1.b). Sectoral estimations provide a more accurate interpretation of this result. Larger firms get progressively less reliant on the economic impact of labour only in the high-tech sectors (Figure 2.d). Their stage of technological development and their relatively smaller average size actually make a (physical) capitalisation process still relevant. Conversely, in the mid-high (Figure 2.e) and low/mid-low tech sectors (Figure 2.f), the technological regimes appear to be so mature and intensive of physical capital that the economic impact of labour remains constant along their size distribution. This is more so for mid-high than low/mid-low tech sectors, whose output elasticity of labour is only about 2/3 of the former.

To summarise, the analysis of the marginal returns of production factors shows important sector specificities in their use/impact for the firms under investigation. With the exception of the high-tech sector, being a top R&D spender (and thus presumably innovative) does not require a shift from physical to knowledge capital with an increase in size to have a greater production impact. The sectoral system of innovation appears more binding in this last respect.

Last but not least, we address the rate of technical progress that the estimate of the production function enables us to detect. A first interesting insight comes from the quantile estimates for the whole sample of top R&D investors (Figure 1.c). Although they all heavily rely on R&D investments (at least in absolute terms) for their innovation activities (top part

of the Scoreboard), their capacity for increasing the level of technological knowledge over time is dependent on their size: the larger the R&D investor, the higher its rate of technical progress. Once linked with the (similar) size dependency that we have found along the whole sample for the marginal return of physical capital (Figure 1.a), this result would suggest an important tentative conclusion. For the firms that we are investigating, the most appreciable kind of technical progress seems to be of an embodied nature. In other words, at least without distinguishing by their economic sector of activity, the technical change of our top R&D investors becomes appreciable (increasing from 1.2% to 2.4%, per year), provided it gets implemented into ameliorated plants and machinery for their production process.

This tentative result is, however, only partially confirmed by the quantile estimates at the sector level. In the low/mid-low (Figure 2.i) and mid-high tech sectors (Figure 2.h), where we also found evidence of a larger relative impact of physical than knowledge capital along the entire size distribution, technical progress increases with firm size, as it is at the aggregated level. In the high-tech sectors, on the other hand, where we previously found unique evidence of a general dominant impact of knowledge over physical capital, the rate of technical progress is nearly constant over the relative size distribution (Figure 2.g).

On the basis of these last results, we can more accurately state that the technological progress of the investigated firms appears embodied, and linked to the advantages that large companies have with respect to small ones in investing in the expansion of their physical capital, in those sectors that appear more traceable to scale-intensive and supply-dominated sectors. In high-tech sectors, by contrast, the size of the firms' plants does not seem to interfere with their rate of technical change. In these sectors, where the economic impact of knowledge capital appears systematically larger than that of physical capital, and the average size is comparatively smaller, the hypothesis of a disembodied kind of technical change seems to be more plausible.

15

Conclusions

Top R&D investors are inherently diverse, not only in the realm of innovation but also in that of production. The quantile estimation of their production function – augmented for the role of knowledge capital – reveals important elements of heterogeneity that standard estimations would otherwise hide. In particular, their size intertwines with their economic sector in specifying some basic, production-related issues, which would otherwise be considered of a general nature for the investigated firms.

This result has important methodological implications for research on the issue. While the use of quantile estimates is becoming increasingly popular for detecting firm-specific factors, our application suggests that the attention given to the heterogeneity deriving from their size should not be viewed in isolation of that originating from the sector in which they operate. Furthermore, our results suggest that technical efficiency measures could by biased when the underlying heterogeneity in the input factors is not taken into account.

Our results also have some interesting policy implications. First of all, although they are all quite large companies, the extent to which our sample of innovative firms benefits from returns to scale is remarkable. Returns to scale appear to be decreasing only for the largest companies of the sample, which are mainly located in the lower tech sectors. In high-tech sectors, on the other hand, returns to scale in production appear exploitable also by large firms. This is of high relevance when we think about policy support to the growth of innovative companies (in our case, innovative investors). While such a stimulus is usually considered suitable mainly for small (and new) technology-based firms, our evidence suggests that large firms could also benefit from it, as they are not constrained by problems of efficiency in production.

Sector-specific effects are also important when we look at the production impact of the different inputs that firms employ. The output of our companies reacts substantially to changes in their knowledge capital only in the case of high tech sectors. Conversely, in lower tech sectors, where firm size is on average higher, physical capital appears to be the pivotal production input along the whole firm size distribution. This is an interesting result when we look at the recent literature (mainly at the country-sector level) about the impact

of tangible vs. intangible assets (e.g. Corrado et al., 2009). By referring to our sample of top R&D spenders, tangible assets appear to count substantially more than intangible ones, unless we refer to firms of smaller size and higher technological level, which are the only ones to appear actually knowledge intensive. Furthermore, the policy implication of this result is quite important and somewhat in line with that obtained by other studies on the same sample of top R&D spenders, which instead focus on their labour productivity (Kumbhakar et al., 2012). Policy support to R&D would have the greatest impact (economic, in our case) in high-tech sectors, whereas the other economic sectors would benefit more from incentives and/or fiscal facilities to physical capital investments. All in all, also by looking at the production realm, policies for innovative firms need to be tailored.

Related to the previous one is the result we obtained for the production impact of labour across the three groups of sectors that we have considered. In mid-high tech sectors, this is on average lower than in high-tech sectors. However, an important distinction appears between the two along their respective size distributions. In the high-tech sector, while that of knowledge capital is size invariant, the output elasticity of labour decreases with firm size, hinting at its substitution by physical capital. This is consistent with a progressively higher degree of automation with increased firm size. In mid-high tech sectors, by contrast, it is the economic importance of labour which remains invariant along the size distribution; the same holds in the low/mid-low tech sectors, although at a lower average level. As we have said, what is noticeable here is rather a size-dependent substitution could accompany those we have provided above, concerning the opportunity of supporting physical capital investments in the lower tech sectors. Because of the maturity stage of the relative technology, this policy support is unlikely to generate labour substitution effects: employment is expected to keep its relevance, independently of firm size.

The need to tailor support to R&D investors on the basis of the relevant production inputs also emerges from the technical progress that our approach enables us to detect. The results we have obtained in this regard are most connected to the innovative performance of our firms and to the innovative policies which can act on it. In the mid-high and low/mid-low sectors, our estimates provide evidence of a technological change of an embodied nature, and for which high intensity of physical capital and large company size provide an

important advantage. Conversely, in high-tech sectors, the opportunities of technical change appear to be of a more disembodied kind, with no advantages for larger firms with larger capital stocks. This last result holds true in the presence of the dominant role of knowledge capital over physical capital, along the whole size distribution. Taking into account the specificities that technical change reveals in different sectors with respect to its embodied and disembodied nature, the need for a sector focus for R&D policies is thus confirmed.

Abstract

The paper investigates how top R&D investors differ in the production impact of their inputs and in their rate of technical change. We use the EU Industrial R&D Investment Scoreboard and perform a quantile estimation of an augmented Cobb-Douglass production function for a panel of more than 1,000 companies, covering the period 2002-2010. The results for the pooled sample are contrasted with those obtained from the estimates for different groups of economic sectors. Returns to scale are bounded by the initial size of the firm, but to an extent that decreases with the technological intensity of the sector. The output return of knowledge capital is the most important, irrespective of firm size, but in high-tech sectors only. Elsewhere, physical capital is the pivotal factor, although with size variations. The investigated firms appear different also in their technical progress: embodied in mid-high and low/mid-low tech sectors, and disembodied in high-tech sectors.

As the Commission's in-house science service, the Joint Research Centre's mission is to provide EU policies with independent, evidence-based scientific and technical support throughout the whole policy cycle.

Working in close cooperation with policy Directorates-General, the JRC addresses key societal challenges while stimulating innovation through developing new standards, methods and tools, and sharing and transferring its know-how to the Member States and international community.

Key policy areas include: environment and climate change; energy and transport; agriculture and food security; health and consumer protection; information society and digital agenda; safety and security including nuclear; all supported through a cross-cutting and multi-disciplinary approach.
